Abstract. We studied structural, optical and magnetic properties of high-quality 5 and 15% Co-doped ZnO films grown by plasma-assisted molecular beam epitaxy (MBE) on (0001)-sapphire substrates. Magnetic force microscopy (MFM) and magnetic measurements with a SQUID magnetometer show clear ferromagnetic behavior of the films up to room temperature, while they are antiferromagnetic below approximately 200 K. Temperature dependences of the carrier mobility were determined using Raman line shape analysis of the longitudinal optical phonon-plasmon coupled modes. It has been show that the microscopic mechanism for ferromagnetic ordering is coupling mediated by free electron spins of Co atoms. These results bring insight into a subtle interplay between charge carriers and magnetism in MBE-grown Zn$_{1-x}$Co$_x$O films.

Keywords: DMS, ferromagnetism, RKKY, plasmon damping.

1. Introduction

Currently one can observe a great interest in understanding and designing the physical properties of diluted-magnetic-semiconductor (DMS) structures. Indeed, they have potential applications in spintronics, where controlling the electron spin can give contribution to new devices. Since theoretical calculations predicted possible room-temperature ferromagnetism (FM) [1] in transition-metal-doped ZnO$_{1-x}$T$_x$O films (T = Cr$^{2+}$, Mn$^{2+}$, Fe$^{2+}$, Co$^{2+}$ and Ni$^{2+}$), they attracted a great interest. Experimental observations of room-temperature FM in V$^{2+}$:ZnO [2], Fe$^{2+}$:ZnO [3], and Co$^{2+}$:ZnO [4] appeared in literature. It seems reasonable to assume that FM is merely due to magnetic impurities, even if some experimental results appeared to rule this out [5]. Up to date, the microscopic mechanism responsible for high-$T_c$ FM is still quite controversial for the II-VI compounds, especially for ZnO based DMSs [6]. Various mechanisms have been proposed for bulk materials, for example, carrier-induced ferromagnetism [1] and percolation of bound magnetic polarons [7]. In addition, structural defects probably play a significant role in controlling the ferromagnetic properties of ZnO. The main reasons referred to in literature for appearance of a ferromagnetic phase are substitution of Zn atoms by the Co ones and existence of magnetic clusters of metallic Co and/or Co oxides in ZnO host. Furthermore, the magnetic properties of Co$^{2+}$:ZnO films have a strong dependence on synthesis and processing conditions [8]. In some cases, even the conclusion of intrinsic ferromagnetism remains controversial [8].

The ferromagnetic properties of 3d-metal-doped ZnO nanoparticles were explained using the core-shell model [9]. High stability of the ferromagnetic phase in Ni$^{2+}$:ZnO nanocrystals was related to a high surface defect concentration [10]. High-$T_c$ ferromagnetism in Mn$^{2+}$:ZnO and Co$^{2+}$:ZnO nanocrystals was interpreted as a result of long-range exchange interaction of Mn$^{2+}$ and Co$^{2+}$ ions mediated by charge carriers [11]. The important role of magnetic anisotropy of Co$^{2+}$ ions in ZnO lattice [12] has been discussed together with clearly observed correlation between magnetism and carrier concentration in Zn$_{1-x}$Co$_x$O films [13]. Nano-scale non-uniform distribution of magnetic ions in the host lattice and spinodal decomposition have been recently observed.
in Cr-doped ZnSe films [14]. The films show ferromagnetic ordering with high values of the Curie temperature.

Three models have been proposed to explain room temperature ferromagnetism in Zn$_{1-x}$Co$_x$O alloys. In the first one, ferromagnetism is mediated indirectly via free carriers (Ruderman-Kittel-Kasuya-Yoshida (RKKY) or double exchange mechanism model). In the second one, ferromagnetism originates from a secondary phase such as metallic Co or Co-oxides. And the latter seems to be related with bound magnetic polarons. In order to clarify this ambiguous situation, we studied the Zn$_{1-x}$Co$_x$O thin films by using magnetic force microscopy (MFM), confocal micro-Raman, photoluminescence (PL) and SQUID techniques.

Raman scattering became a very useful and informative technique for studying different phonon excitations in undoped and doped by Li, N, Fe, Sb, Ga, Al ZnO films. It allows studying the influence of structural disorder in ZnO lattice on vibrational properties [15]. The study of Co – O – Zn local vibration modes versus concentration of oxygen vacancies [16] allows correlating carrier concentration and magnetic properties. Appearance of phonon bands at 186, 491, 526, 628, and 718 cm$^{-1}$ was interpreted as an indication of Zn$_{1-x}$Co$_x$O$_4$ [17] spinel phase. Note that nanometer-size Zn$_{1-x}$Co$_x$O$_4$ clusters can be very easily detected in micro-Raman measurements whereas X-ray diffraction method is not well suited for studying these small clusters.

In the absence of magnetic secondary phases, the distribution of Co$^{2+}$ ions on cation sites of ZnO lattice should play an important role for ferromagnetism. A substituting Co$^{2+}$ ion in the Zn site can have no Co second first neighbor, i.e., it is not involved to one (several) Co – O – Co sequence(s) or has at least one Co second neighbor. The magnetic properties have a strong dependence on the number of Co atoms of the first type (isolated atoms). Assuming that Co atoms are randomly distributed over cation sites and neglecting antisite and interstitial-site occupation, it was shown for the 5 and 15%Co-doped ZnO films that 94 and 14% of Co atoms, respectively, belong to the first type. Note that the assumption rules out metallic Co clusters [18-21]. It is expected that isolated Co atoms have ferromagnetic interaction mediated by free carriers. In the Co – O – Co bonding configurations, the two neighboring Co localized spins are assumed to be coupled antiparallel providing antiferromagnetic properties, especially at low temperature [8, 18-21]. As a result, there is a competition between a ferromagnetic and anti-ferromagnetic interactions in the Zn$_{1-x}$Co$_x$O films. It is expected that ferromagnetic interactions between Co$^{2+}$ ions should take place in high quality Zn$_{1-x}$Co$_x$O films with high electron concentrations ($n > 10^{19}$ cm$^{-3}$) [21].

This paper is organized as follows. Section II describes the growth procedure and setup for micro-Raman, MFM and magnetic measurements. In Section III, we focus on the magnetic, structural, optical and electronic properties of the MBE-grown 5% and 15% Co-doped Zn$_{1-x}$Co$_x$O thin films. Using the MFM and SQUID technique, magnetic interactions in the films are studied. In the films, a broad emission peak at 1.816 eV (683 nm) is ascribed to electron transitions within substitutional Co$^{3+}$ ions. These results confirm that the Co$^{3+}$ ions are located at the Zn sites in the wurtzite ZnO structure. The micro-Raman measurements confirm the crystalline wurtzite structure in Co-doped ZnO films. Also, the temperature-dependent Raman measurements of longitudinal optical phonon-plasmon coupled modes (LOPCMs) were performed. Modeling the Raman spectra for LOPCMs allows determining the temperature dependence of the carrier mobility. The results show that ferromagnetism in Zn$_{1-x}$Co$_x$O films is due to free carriers with high mobility and supports an indirect interaction of localized magnetic moments of isolated Co$^{3+}$ ions in the ZnO lattice. Section IV is devoted to summary and outlook.

2. Experimental details

The Zn$_{1-x}$Co$_x$O films were grown on c-sapphire substrates in a Riber Epineat MBE system equipment with conventional effusion cells for elemental Zn and Co. Atomic oxygen was supplied via an Addon radio-frequency plasma cell equipped with a high-purity quartz cavity [19]. The film thickness was about 1.7 μm. The epilayer crystalline quality was attested by low full-width-at-half-maximum values in high-resolution X-ray diffraction scans for high-symmetry as well as oblique directions (see Table I). Lattice parameters of the pure ZnO sample match well with the values of ZnO single crystal ($a = 3.2495$ Å, $c = 5.2069$ Å). After Co substitution with Zn atom, both $a$- and $c$-axis lattice constants are changed ($a = 3.266$ (3.259) Å and $c = 5.197$ (5.195) Å for 5 (15) at.% Co). Some discrepancy between the concentrations determined using contactless submicrometer Raman and macro-Hall measurements (Table I) can be caused by differences in local regions of measurements and possible changes of electric parameters due to heating under contact formation for Co-doped ZnO films.

Confocal micro-Raman and PL measurements were performed using the 488.0 nm line of the Ar$^+$ /Kr$^+$ laser and recorded with a Jobin-Yvon T64000 spectrometer equipped with a CCD detector. Spatial resolution (lateral and axial) was about 1 μm. The temperature-dependent micro-Raman spectra (80-500 K) were obtained using a Linkam THM600 temperature stage.

The MFM measurements were performed by Dimension 3000 Nano-Scope IIIa scanning probe microscope for spatial mapping of the magnetization structure of the out-of-plane component of the magnetic stray field of the Zn$_{1-x}$Co$_x$O sample surface at room temperature. Before measurements, the probe was magnetized using a strong permanent magnet with the field aligned along the tip axial axis. Then the MFM images of the sapphire substrate surface were taken, and
no magnetic signal was registered. The magnetic force gradients were measured using a two-pass technique (Lift Mode), where the topography was scanned at the first pass in the tapping mode and then magnetic field gradients were obtained using the oscillation frequency shift of the probe moving over surface. The cobalt coated Veeco magnetic tips with a coercivity of $\approx 400 \text{ Oe}$, magnetic moment of $\approx 10^{-13} \text{ emu}$ and 25 nm nominal tip apex radius were used. The two opposite orientations of probe magnetization were used (i.e. North or South pole on the tip apex). This allows distinguishing the signal of the gradient magnetic fields from other artefacts of long-range electrostatic fields detected by the magnetic tip apex. The value of lift scan height was optimized for maximal sensitivity and minimal topography effects and was about 100 nm. The chip structure of Zn$_{1-x}$Co$_x$O samples were also studied using a ZEISS EVO-50 scanning electron microscope (SEM). The magnetic measurements were carried out using a Quantum Design SQUID magnetometer MPMS-XL5.

* The accuracy of determining the carrier concentration from analysis of modelled o$^+$ LOPCM was about ±20%.

3. Results and discussion

AFM is used to characterize surface morphology, root-mean-square (rms) roughness, and to verify the microstructures of Zn$_{1-x}$Co$_x$O films. AFM morphology image of Zn$_{1-x}$Co$_x$O films in the regions of chipped film edge changes with increase of the Co concentration (Fig. 1). As seen from Fig. 1a, morphology of 5%-doped ZnO films shows very tiny crystal grains (20–30 nm) due to the vertical columnar growth mode and the rms roughness of about 1.8 nm. For 15% Co-doped ZnO films (Fig. 1b) the rms roughness is close to 2 nm, the larger domain structures with sizes from 100 to 400 nm are formed by binding the smaller crystal grains. Let us note that in this case the smaller crystal grain size is practically unchanged with increasing the Co concentration. Similar morphology was reported for Co- and Al-doped ZnO films [22, 23].

The surface sensitive MFM method was used to study magnetization in the vicinity of the chipped sample edge of the Co-doped ZnO films. We deal with the area of pure substrate and sharp film edge (Fig. 2). As seen from the profiles (Fig. 2c), magnetization of the 15%Co-doped ZnO film exhibits a sharp jump in magnetic signal at the chipped edge for the South and North pole of the probe (Fig. 2a,b). The MFM magnetization map is independent of the AFM topography image of the Zn$_{1-x}$Co$_x$O surface films. For the 5%Co-doped ZnO film, similar changes in the MFM image take place, but changes are not so sharp, and their value is ~10 times lower than for the 15%Co-doped ZnO film (Fig. 2c).

Fig. 1. 3 × 3 μm$^2$ AFM images for ZnO films doped with 5% (a) and 15% (b) on the sapphire substrate. The inserts show SEM (left) and 3D AFM (right) images of the chipped edge.
from Fig. 3 that the temperature dependences for undoped and 15%Co-doped ZnO films drastically differ. The observed higher value for magnetization of 15%Co-doped ZnO film is caused by strong interaction between Co$^{2+}$ ions with the magnetic moment close to $3\mu_B$ per Co$^{2+}$ ion in Zn$_{1-x}$Co$_x$O film [12, 19]. The magnetic susceptibility in the undoped ZnO film is negative (Fig. 3) and practically does not depend on temperature. For the 15%Co-doped sample one can observe a strong dependence of the magnetic susceptibility on temperature that is described with the Curie-Weiss law. The diamagnetic contribution $\chi = C/(T - \Theta) + \chi_{\text{sub}}$, where $C$ is the Curie constant, $\Theta$ — Curie-Weiss temperature, and $\chi_{\text{sub}}$ — diamagnetic susceptibility of substrate, were taken into account when analyzing SQUID data for the Co-doped samples. As a result, for the undoped ZnO film we obtained low magnetization values $< 0.1\mu_B$ magnetic moment per defect, which is often related with oxygen vacancies [25]. Weak ferromagnetism for undoped ZnO film is clearly demonstrated by magnetization reversal loops in the insert of Fig. 3. For the case of Co-doped ZnO films, the obtained results for magnetization are shown in Figs 4 and 5 with account of the substrate diamagnetic contribution.

Peculiarities of hysteresis curves of the Zn$_{1-x}$Co$_x$O samples are observed in magnetization measurements up to 300 K (Fig. 4). The temperature dependence of inverse magnetic susceptibility in magnetic field of 1000 Oe is shown in Fig. 5. The magnetic susceptibility has two well distinguished temperature regimes (at low (LT) and high (HT) temperatures, respectively) with a typical Curie-Weiss behavior for both $H \perp c$ and $H \parallel c$ geometry of magnetic field. The Curie temperatures $\Theta$ obtained from extrapolation to the temperature axis show clearly the HT and LT regimes of effective magnetic interactions (Figs 5 and Table II). As a result of the dominant ferromagnetic interactions between the Co$^{2+}$ ions, one can observe hysteresis loops with coercivity values of $H_c \approx 20$ Oe and $H' \approx 10$ Oe at 300 K (inserts in Fig. 4). On the other hand, at low temperature ($T < 200$ K), one obtains a negative Curie-Weiss temperatures (Fig. 5 and Table 2), which can be considered as a result of antiferromagnetic behavior of Co$-O-CO$ sequences and has been previously observed for the Zn$_{1-x}$Co$_x$O films [19, 20] and powders [26]. So, when analyzing the magnetic properties of Co-doped ZnO films, the change in magnetic behavior of the Zn$_{1-x}$Co$_x$O films can be understood as a result of competition between the ferro- and antiferromagnetic Co interactions that are caused with to isolated Co ions and Co$-O-CO$ sequences [20, 21], respectively. Effective indirect exchange interaction between isolated Co$^{2+}$ ions decreases with decreasing the carrier mobility, and at low temperatures the dominant magnetic interaction is antiferromagnetic due to Co$-O-CO$ sequences. The carrier concentration in our films is $\sim 10^{20}$ cm$^{-3}$ at any temperature. This value was estimated from the LOPCM in the Raman spectra. Therefore, for these high
quality MBE-grown Zn$_{1-x}$Co$_x$O films, the high-temperature ferromagnetism is expected to be related with to the high electron concentration in the conduction band.

It is well known that for Zn$_{1-x}$Co$_x$O films the magnetization curves at low magnetic field, which is a more favorable for ferromagnetism observation, can be different from the prediction of the effective spin model [19] used for interpretation of the para- and antiferromagnetic Co behaviors. For the studied films, the magnetization (Fig. 4) and magnetic susceptibility (Fig. 5) curves reveal the presence of significant magnetic anisotropy with the magnetic moment $M \perp c$ as observed in Refs [19, 20]. The fact that $M \perp c$ is higher than $M \parallel c$ at low temperatures is in good agreement with theoretical predictions that antiferromagnetic interactions of Co–O–Co sequences are less stable than ferromagnetic interactions along the $c$ direction [10, 27]. The ferromagnetic interaction in this direction is more favorable for ferromagnetism, at least for temperatures above 200 K, as observed in our SQUID measurements (Fig. 5).

Fig. 4. Magnetization of the Zn$_{1-x}$Co$_x$O film with $x = 15\%$ versus magnetic field. $M(H)$ were taken at 5 (squares) and 300 K (circles) with $H \perp c$ (filled symbols) and $H \parallel c$ (open symbols) geometry of a magnetic field, respectively. The inserts show the region near the zero field for both geometries in more details.

Fig. 5. Inverse magnetic susceptibility of the Zn$_{1-x}$Co$_x$O film with $x = 15\%$ versus temperature at the magnetic field $H = 1000$ Oe with $H \perp c$ (filled square) and $H \parallel c$ (open triangle) geometry.

Fig. 6 shows PL spectra of undoped (curve 1) and Co-doped (5 and 15\%Co, curve 2 and 3, respectively) ZnO films at $T = 300$K (in insert at $T = 6$ K). In the PL spectra of undoped ZnO films, a broad green emission band is observed at ~ 2.18 eV, which is associated with intrinsic deep-level defects in ZnO, namely: oxygen vacancies, interstitial zinc atoms, and antisite oxygen atoms [10, 28]. For 5\%Co-doped ZnO, the red emission peak at ~ 1.816 eV (683 nm) (Fig. 6, curve 2) corresponds to electron transitions between d-levels [29] of isolated Co$^{2+}$ ions tetrahedrally coordinated to oxygen atoms. Increasing the Co concentration to 15\% induces a red-emission weakening due to decrease in the amount of isolated Co$^{2+}$ ions and increase of Co – O – Co sequences [8, 18] that don’t contribute to the red band emission. In addition, the effect of decreasing the intensity of red emission cannot be related with the formation of secondary phases such as octahedral Co oxides, since no indication of additional structure phases
Raman measurements were performed to analyze the vibrational modes and lattice structure of the Co-doped ZnO films. They confirm that the films do have the wurtzite structure. Indeed, Fig. 7 exhibits micro-Raman spectra taken from an undoped (curve 1) and Co-doped (5 and 15%Co, curves 2 and 3, respectively) ZnO films. According to group theory, four Raman-active modes, 

\[ E_1^\text{low}, E_1^\text{high}, E_2^\text{low}, E_2^\text{high} \]

are expected for the wurtzite-type ZnO structure, which belongs to the space group \( P6_3mc \). The polar nature of \( E_3^\text{low} \) and \( E_1 \) modes leads to a splitting into TO and LO components. The \( E_2^\text{low} \) and \( E_2^\text{high} \) modes are non-polar. In the backscattering geometry for (0001) ZnO, both \( E_2 \) and \( A_1(g) \) modes can be detected. The \( A_1(g) \) (LO) mode at \( \approx 574 \text{ cm}^{-1} \) shows a very low intensity for high-quality ZnO films. The most pronounced peaks in ZnO originate from \( E_2^\text{low} \) and \( E_2^\text{high} \) phonon modes at \( \approx 100 \) and \( \approx 437 \text{ cm}^{-1} \), respectively. The \( E_2^\text{high} - E_2^\text{low} \) modes are observed at \( \approx 333 \text{ cm}^{-1} \). Fig. 7 illustrates also the presence of three phonon modes of the sapphire substrate (denoted by asterisks) with the \( A_{1g} \) (418 cm\(^{-1}\)) and \( E_g \) (379 and 578 cm\(^{-1}\)) symmetries, respectively.

The Raman non-polar \( E_2^\text{low} \) and \( E_2^\text{high} \) modes in undoped ZnO films are very sensitive to disorder in zinc and oxygen sublattices, respectively. According to Fig. 7 (curve 1), for undoped ZnO films the \( E_2^\text{low} \) mode at \( \approx 100.5 \text{ cm}^{-1} \), involving mainly Zn motion, displays a very narrow linewidth \( \approx 1.6 \text{ cm}^{-1} \). After Co doping, the \( E_2^\text{low} \) mode intensity strongly decreases. The mode is broadened up to \( \approx 2.4 \text{ cm}^{-1} \) and undergoes a red shift (up to \( \approx 0.7 \text{ cm}^{-1} \)) with respect to undoped ZnO. It is the effect of compositional fluctuations induced by random substitution of Co ions into Zn sites in host lattice. Such an alloying effect does not usually involve any precipitation of other crystalline phases and occurs, for example, in (Ga, In)N, where In-rich quantum-dot-like regions arise [30]. The spectra also exhibit an intense \( E_2^\text{high} \) mode associated with oxygen-atom vibrations which appear at \( \approx 439.5 \text{ cm}^{-1} \) with a full-width-at-half-maximum \( \Gamma \approx 5 \text{ cm}^{-1} \) for undoped ZnO film. With the increase of Co amount, the \( E_2^\text{high} \) mode shows a red shift up to \( \approx 1.2 \text{ cm}^{-1} \) and broadens up to \( \approx 13 \text{ cm}^{-1} \) due to disorder effects in the oxygen sublattice (vacancies, interstitials) inducing a change in coordination numbers of some Co atoms due to oxygen vacancies.

In the Raman spectra of most heavily doped ZnO, there is often observed the intense signal in the region between TO and LO modes, the interpretation of this band is ambiguous. For Co-doped samples, additional overlapping the broad and intense bands in the region of 450-580 cm\(^{-1}\) is detected (Fig. 7). These bands were observed in different scattering geometries and therefore could be attributed to the ZnO phonon states due to disorder-activated Raman scattering [31]. It is also assumed [32, 33] that for Co-doped ZnO nanostructures a broad feature at 470-500 cm\(^{-1}\) may be assigned to the surface optical phonon mode (SOP) (Fig. 7). When the crystallite size of ZnO lies within the range \( 10 \text{ nm} < L < 100 \text{ nm} \), the SOP can appear, and its intensity increases with reducing the nano-column diameter [34]. It is noteworthy that the SOP peak is reliably detected in resonant multi-phonon Raman spectra (\( E_{\text{exc}} = 3.81 \) eV) of undoped and Co-doped ZnO films, the frequency of this mode being independent of the Co concentration (is not shown). Difficulties in SOP detection in non-resonant Raman spectra of undoped ZnO films can be also caused both by large crystallite sizes (150-200 nm) and considerable disordering at the boundaries of the internal grain structure, as compared with Co-doped films.

Additional bands at \( \approx 488, 550 \) and \( \approx 708 \text{ cm}^{-1} \) in Co-doped bulk samples and thin ZnO films grown by various methods have been reported in the literature [17, 35]. These bands arise from secondary structural phases. They can be clusters of \( \text{Co}_2\text{O}_3 \) or isometric compounds \( \text{Zn}_3\text{Co}_2\text{O}_6 \). However, in our samples, additional Raman bands of these secondary phases are not present.
An intense wide band appears in the frequency range of 550–600 cm$^{-1}$ for the Co-doped samples (Fig. 7). At least two Lorentzian profiles are necessary for fitting the band which splits into two subbands at 15%Co and 5%Co, respectively. It is interesting to note that with increasing the Co concentration from 5 to 15%, the intensity of both modes is substantially increased. This gives a clear evidence for the Co substitution in ZnO host lattice [17]. A similar increase in the intensity of the Raman band was reported for the multiphonon mode at 540 cm$^{-1}$ and $E_{2}(LO)$ mode at 584 cm$^{-1}$ in Co-doped [17] ZnO. In our opinion, these bands are related with the resonant effect at subband excitation caused by $d$-$d$ transitions in Co$^{2+}$ ions as well as by defect levels in ZnO host within the energy range 2.2–3.0 eV [36]. The extrinsic Fröhlich interaction mediated by the localized electronic states bounded to defect, impurities and $d$-related levels of Co$^{2+}$ ions could enhance the scattering efficiency independently on the phonon wave vector $q$.

The zone-center LO phonons are affected by the $n$-type conductivity which is due to the oxygen vacancy ($V_O$) and interstitial Zn (Zn$^+$) [37] of the Co-doped ZnO films, since we deal with electron concentrations higher than $10^{20}$ cm$^{-3}$. In polar semiconductors, when the frequency of longitudinal plasma oscillations approaches the LO phonon frequencies, their macroscopic electric fields strongly interact, which results in appearance of the $\omega$ and $\omega$ LOPCMs. However, owing to poor carrier mobility of the doped ZnO epiayers, it is expected that the LOPCMs are overdamped due to existence of many structural defects.

In order to assign the bands in films with 5 and 15%Co at ~ 342 cm$^{-1}$ and ~ 368 cm$^{-1}$, respectively, to plasmon modes, we performed the Raman measurements at temperatures from 80 to 500 K (Fig. 8) analyzing the band shapes by using the semiclassical theory of Raman scattering [38]. Both the electro-optic and deformation potentials ($I^{EO}$ and $I^{DF}$) as well as charge-density ($I^{CD}$) contributions to the processes of light scattering were taken into account. The $\omega$-plasma-like modes are fitted by using the following set of equations:

$$I(\omega) = A_1 I^{DF} + A_2 I^{CD}(\omega) =$$

$$\left( A_1 \left[ \frac{\omega_T^{2} + (1 + \chi_{FH}) - \omega^2}{\omega_T^{2} - \omega^2} \right] + A_2 \left[ \frac{\omega_T^{2} - \omega^2}{\omega_T^{2} - \omega^2} \right] \right) \times \text{Im} \left( \frac{-1}{\varepsilon(\omega)} \right),$$

$$\varepsilon(\omega) = \varepsilon_{\infty} + \varepsilon_{\infty} \frac{\omega_T^{2} - \omega^2}{\omega_T^{2} - \omega^2} - \frac{\omega_T^{2} - \omega^2}{\omega(\omega - i\gamma)},$$

where $\varepsilon_{\infty}$ is the high-frequency dielectric constant, $\chi_{FH}$ is the Faust-Henry coefficient, $\omega_{TO}$ and $\omega_{LO}$ are frequencies of LO and TO phonons, $\Gamma(\gamma)$ is a phonon (plasmon) damping coefficient, $\omega_{p}$ is the plasmon frequency.

We used the prefactors of $\text{Im}(-1/\varepsilon)$ in Eq. (1) for the light-scattering efficiency from Ref. [38]. By using the optimization procedure for the $\omega$ plasma-like mode [38], one finds the $A_1$, $A_2$ coefficients and the $\gamma$ parameter for which the sum of the $\chi^2$ values, $\Sigma(\chi^2_{\omega}(\omega) - I(\omega))^2$ is minimal at fixed $\omega_{p}$ and $\gamma$ values. The $\omega$ band shape fitting analysis was made for each of the Raman spectra at a given temperature in order to get the plasmon damping, $\gamma$ versus temperature.

Two calculated LOPCMs modes (dashed lines) are shown in Fig. 8 and demonstrate very good agreement with the experimental spectra. For modeling the $\omega$ LOPCMs band, we used the following parameter values: $C = 6.4$ [39], $\omega_{TO} = 381.6$ cm$^{-1}$ and $\omega_{LO} = 574.2$ cm$^{-1}$, $\varepsilon_{\infty} = 3.67$ and the effective mass of electron $m^* = 0.27m_0$ where $m_0$ is the electron mass in vacuum. The plasmon damping value provides the carrier mobility value ($\mu = e/m^* \gamma$), and the plasma frequency $\omega_{p}$ is related with the carrier concentration $n$ by the relation $\omega_{p} = 4\pi e^2 n/\varepsilon_{\infty} m^*$. Therefore, one can obtain also the carrier mobility value, $\mu$, versus temperature.

Fig. 9 shows the temperature dependence of the electron mobility for the Zn$_{1-x}$Co$_x$O films with 5 and 15%Co, respectively, obtained from modeling the $\omega$ LOPCMs band. We found $\omega_{p}$ and $\gamma$ values equal to 3400 cm$^{-1}$ and 47 cm$^{-1}$, respectively, at any temperature. The value of $\omega_{p}$ corresponds to the electron concentration $1.3 \times 10^{20}$ cm$^{-3}$. This high value for $\omega_{p}$ is in good agreement with a spectral position of the $\omega$ LOPCMs ($\omega_{p} \approx \omega$) observed in the experimental Raman spectra for the Zn$_{1-x}$Co$_x$O films with 5% and 15%Co (see insert in Fig. 7). The plasmon damping parameter $\gamma$ has a strong temperature dependence, which arises from the temperature dependence of the electron mobility. In order to determine the influence of ferromagnetic ordering on the carrier mobility, we calculate contributions to the mobility, which are due to the carrier scattering process on the acoustic $\sim (kT)^{1/2}$ and optic $\sim (\exp(h\omega_\omega/kT) - 1)$ phonons (Fig. 9) in high quality epitaxial undoped ZnO films [37]. Even if the mobility in our Zn$_{1-x}$Co$_x$O films decreases with the temperature increase up to 500 K, its value is comparable to that in structurally perfect ZnO films at temperatures around 500 K. It is interesting to note that the electron mobility in the films with 15%Co is higher than that with 5%Co at any temperature (Fig. 9). Correlation between magnetic and transport properties was published for DMS based on A$^3$B$^2$ semiconductors [40]. For example, for p-GaMnAs the maximum value of Curie temperature ($T_C = 110$ K) was obtained for a metallic type conductivity and with a higher value of the charge carrier mobility [40]. This correlation between magnetic properties and electron mobility takes place in the studied Zn$_{1-x}$Co$_x$O films, too (Fig. 9).
Up to date, the physical mechanism of ferromagnetic ordering in $n$-type Zn$_{1-x}$Co$_x$O is not ascertained yet. One can offer the following microscopic mechanism of ferromagnetism related to the electron concentration in the conduction band. The mechanism foresees long-range interaction between two localized magnetic moments $\vec{S}_i$ and $\vec{S}_j$ of isolated Co$^{2+}$ ($S = 3/2$) ions at a distance of $|\vec{R}_i - \vec{R}_j|$ via free electrons in the conduction band. For these magnetic moments, an important role is played by the parameter of exchange interaction $J_{ij}$ that can oscillate in the direct space, as for RKKY interaction mechanism [40, 41]. The exchange interaction $J_{ij}(\vec{R}_i - \vec{R}_j)$, which is responsible for the Curie temperature, depends on the electronic subsystem of Zn$_{1-x}$Co$_x$O semiconductor [41]. For the samples to be ferromagnetic, most of the Co-atom spins should be parallel one to another. In other words, the symmetry of the total system including the crystalline lattice and Co-atom spins should be higher in the ferromagnetic phase.

Since the symmetry of the total system for the ferromagnetic phase is maximal, one should expect larger electron mobility than for a disordered configuration. However, the situation is more complex for the studied anisotropic wurtzite Co-doped ZnO films. There takes place considerable anisotropy of magnetization with the easy-axis magnetization $H \perp c$ [12, 19] (Fig. 4).

For ferromagnetic phase of Co-doped ZnO films ($H \perp c$, $T > 40$ K, Table 2), we performed the analysis of Raman spectra of LOCPMs and found an increase of the carrier mobility with decreasing temperature (Fig. 9). This effect could be explained by phonon mechanism of the carrier scattering [37]. Note that the carrier mobility (and magnetization) is higher for 15% sample as compared with 5% sample (Fig. 9). It remains to explain why ferromagnetism takes place only at rather high temperatures. One can suggest that coupling between electron spins and Co-atom spins is favored by collisions with phonons. Phonon population increases with temperature which increases the collision probability.

4. Summary and outlooks

In this work, we have studied magnetic, structural, optical and electron properties of high quality MBE-grown Zn$_{1-x}$Co$_x$O films with $x = 0$ (undoped), $x = 5\%$ and $x = 15\%$. We provide experimental evidence for important role of electrons that enhance ferromagnetism with Curie temperature up to the room one.

From MFM magnetization maps and SQUID measurements, ferromagnetic behavior of films at room temperature is clearly put into evidence. SQUID data show a complicated temperature dependence of the magnetic susceptibility, which is due to two different kinds of coordination, at the range of second first neighbors, for Co$^{2+}$ ions within the ZnO host. Co–O–Co sequences contribute to antiferromagnetic behavior whereas isolated Co$^{2+}$ ions contributes to ferromagnetic properties of the films. High temperature ferromagnetism results from interaction between isolated ions at cation sites mediated by conduction electrons.
(RKKY-like mechanism). On the contrary, at low temperatures (temperatures below 150 K), the antiferromagnetic effect of Co – O – Co sequences is dominant.

The Raman measurements confirm the high crystalline quality of both undoped and Co-doped ZnO films as well as their wurtzite structure. Raman bands of the antiferromagnetic Co oxygen spinel clusters have not been observed. The red Co emission exhibits a broad peak at 1.816 eV (683 nm), which can be ascribed to electron transitions within isolated Co$^{2+}$ ion.

Raman investigation of LOPCMs versus temperature has been used to probe the free-carrier properties in films. A modeling of the $\omega$ LOPCM band was performed, which allows determining the temperature dependence of the charge carrier mobility. Curie temperature increases with the Co concentration within the range 5% to 15%, and the magnetic films with a higher value of magnetization have a higher electron mobility.
