Abstract. A new iterative Fourier transform method of synthesis of kinoforms is presented. Two object-depended filters (an amplitude filter and a phase one) are used in the object plane on the iterative calculation of a kinoform instead of a single (phase) filter as usual. The amplitude filter is a system of weight coefficients that vary in the process of iterations and control the amplitude of an input object. The advantages of the proposed method over other ones are confirmed by computer-based experiments. It is found that the method is most efficient for binary objects.

Keywords: digital holography, holographic optical elements, phase retrieval, phase-only elements.

1. Introduction

There exists a high number of iterative algorithms aimed at the solution of phase problems, including the problem of a kinoform. The majority of algorithms was developed on the basis of the so-called error-reduction (ER) algorithm [1]. It was refined in works by Fienup [2, 3] on solving the problems of star interferometry (a group of input-output algorithms). I mention also the subsequent works, e.g., by Wyrowski and Bryngdahl [4], Wyrowski [5], and Yang, Gu [6] in which the iterative algorithms were further improved. At the present time, all they form a family of the so-called iterative Fourier transform (IFT) algorithms. The comparative analysis of a number of algorithms from this family is available in some surveys (see, e.g., [7, 8]).

It is known that processing the amplitude of a field (A-field) in the spectral plane is the same in all IFT algorithms of calculation of a kinoform. This operation is nonlinear and consists in the reduction of the A-field to unity. The algorithms differ from one another by a mean of processing the field in the object plane which depends on the final purpose, namely, on a function which should be realized by a kinoform (the beam splitting, beam shaping, image generation, and so on). It is worth to note that, despite the diversity of operations used in the object plane, all they, are linear (except the ER-algorithm).

2. Algorithm

In the present work, I give a modified ER-algorithm of calculation of a kinoform, whose main unique distinction from the classical ER-algorithm [1] consists in the use of a new nonlinear operation [9] of processing the A-field in the object plane. This operation in its complex-valued version was used earlier by us in the synthesis of double-phase holograms [10]. To clarify its application, the work of the algorithm is illustrated in Fig. 1. First, one or several iterations (\(K_0\)) are realized by the classical ER-scheme which requires no explanations. Then, in all iteration with \(k > K_0\) on the formation of an input, \(f\) will be replaced by a new function defined as

\[
 f_k = \alpha_k f,
\]

where the weight coefficients \(\alpha_k\) are determined by the recurrence relation

\[
 \alpha_k = \alpha_{k-1} \beta_{k-1} \quad (k > 1),
\]

\[
 \beta_{k-1} = f / |g_{k-1}| + \varepsilon.
\]

Here, \(|g_{k-1}|\) is the reconstructed amplitude on the \((k-1)\)th iteration, and \(\varepsilon\) is a small number \(\sim 10^{-10}\) excluding the division by zero. It should be mentioned that \(f\) is real. Operations (1)-(3) are heuristic and have no strict mathematical justification. The physical sense of
the coefficients $\alpha_k$ becomes clear if the block of the algorithm separated by a dashed line in Fig.1 is considered, according to Fienup [3] as a nonlinear unit with the input $\exp(ip)$ output $g$, and action operator $F^{-1}C kup F^{-3}$. From the viewpoint of the theory of image-processing system, the coefficients $\alpha$ is nothing but the collection of coefficients of a negative feedback “output-input”; if the amplitude $g_{k,i}$ on the $(k-1)$th iteration at some point $(x, y)$ of the plane of images is more than a given value $f$, then, on the next $4$th iteration, the input $f$ at the corresponding point $(x, y)$ will be corrected. Namely, it will be decreased by $a_k$ times, and vice versa. At the same time, from the viewpoint of optics, the system of coefficients $a_k$ normalized to unity can be interpreted as some object-depended amplitude filter which acts on the initial object $f$ and varies in the process of iterations. It is clear that, for all ER-iterations, $\alpha(x, y) = a_k(x, y) = 1(x, y)$.

3. Experiment

A number of model experiments with various objects was realized with the purpose to study the potentialities of the method. For the sake of comparison, analogous experiments were also performed with the use of a kinoform version of the input-output (IO) algorithm by Fienup [3]. In all the cases, the same phase starting diffuser with a uniform distribution of phases in the interval $0-2\pi$ is used. The variance of the amplitudes of images reconstructed in the process of iterations was evaluated using the formula

$$\sigma_g(k) = \frac{\sum_{l,m} (f_{l,m} - \mu(k))|g_{l,m}(k)|^2}{\sum_{l,m} (f_{l,m})^2},$$

where

$$\mu(k) = \left(\frac{\sum_{i,j} (f_{i,j})^2}{\sum_{i,j} |g_{i,j}(k)|^2}\right)^{1/2}$$

is the scale factor, the indices $l, m$ and $i, j$ run over the points, where the amplitude of an initial object $f$ is nonzero, and $k$ is the iteration number.

In the experiments involving the IO algorithm, the optimum value of the object-depended coefficient $\beta = \beta_{opt}$ in the equations for the input function (see Eqs (8) and (9) in Ref. [3]) is used by attaining the best behavior of the function $\sigma_f(k)$ during iterations in all the cases. The value of $\beta_{opt}$ was determined by means of the cyclic repetition of the procedure of synthesis for various values of $\beta$ (from the interval 0.1-5.0 with a step of 0.1).

In Figs 2 to 4, the results of model experiments on the synthesis of the kinoforms of binary and halftone objects with a dimension of $64 \times 64$ counts are presented.
At the same time, the IO algorithm (with optimized \( \beta \)) “stops” at the value \( \Delta I_{\text{one-bit}} = 2.5 \times 10^{-5} \). That is, it falls in a minimum of \( \sigma_g(k) \) which is quite deep, but, nevertheless, is local. As for the ratios of the minimum one-bits-intensity to the zero-bits intensity for three algorithms, they are equal, respectively, to 4 (ER), 4.53 (IO), and 7 (weighting). Figure 3b demonstrates the effect of diminution of the variance \( \sigma_g(k) \) on the transition from one algorithm to another one. Analogous results were obtained also for other binary objects with dimensions of 64×64 and 128×128.

3.2. Halftone object

A somewhat more complicated situation is observed for halftone objects, one of which is presented in Fig. 2b. As was shown by model experiments, the kinoforms of such objects calculated with the help of the weighting algorithm reconstruct a high-quality image only in the range of amplitudes from ~0.15 to unity (on the normalization of the image to unity). The rest amplitudes are distorted to a variable degree. The proper normalization of the image to unity). The rest amplitudes range of amplitudes from ~0.15 to unity (on the normalizatoin of the image to unity). The rest amplitudes range of amplitudes from ~0.15 to unity (on the normalizatoin of the image to unity). The rest amplitudes range of amplitudes from ~0.15 to unity (on the normalizatoin of the image to unity). The rest amplitudes range of amplitudes from ~0.15 to unity (on the normalizatoin of the image to unity). The rest amplitudes range of amplitudes from ~0.15 to unity (on the normalizatoin of the image to unity).

Fig. 4. Variance of amplitude of the reconstructed images for halftone object without and with a base (Fig. 2b, c).

The calculated efficiencies of kinoforms (in parentheses, the values obtained within the IO algorithm are given) are as follows: 91.39 (91.25) % for the object in Fig. 2a, 94.82 (92.48) % for the object in Fig. 2b, and 96.91 (95.02) % for the object in Fig. 2c.

In the course of calculations, the criticality of the weighting algorithm with respect to a value of the parameter \( \varepsilon \) in the formula (3) is verified. By varying \( \varepsilon \) from \( 1 \times 10^{-7} \) to \( 1 \times 10^{-6} \), the deviation of \( \sigma_g(\varepsilon) \) from \( \sigma_g(\varepsilon_{10}) = 10^{-10} \) is determined by the formula

\[
\Delta \varepsilon = 100 \% [\sigma_g(\varepsilon) - \sigma_g(\varepsilon_{10})]/\sigma_g(\varepsilon_{10})
\]

for various objects with the number of iterations equal to 50. On the average, \( \Delta \varepsilon \) was (0.002-0.05) %. Thus, the variation of \( \varepsilon \) in the indicated limits did not influence practically the exactness of the calculation of a kinoform and, at the same time, excluded the situation where one should divide the numerator in formula (3) by zero.

3.3. Super-Gaussian (SG) beam shaping

Within the weighing and IO algorithms, the calculations of kinofoms that are the transducers of the intensity of a Gauss beam of the form \( \exp[-(x^2 + y^2)/2r_0^2] \) in a SG beam of the form \( \exp[-(x^2/r_0^2)^M - (y^2/r_0^2)^M] \) are performed, where \( r_0 \) and \( r_0' \) are the inflection radii of the Gauss curves, and \( M \) is the SG order (as known, the calculation of a kinoform involves the square root of the both indicated intensities). In Fig. 5, the input \( (r_0 = 70) \) and the output \( (r_0' = 25) \) intensity profiles for \( M = 4 \) and \( M = 100 \) with a dimension of the object (kinoform) of 256×256 counts are presented. The iteration process with \( K_{\text{er}} = 10 \) was truncated at the 100th iteration. With regard for the separation of the working part of a SG beam so as shown in Fig. 5, the intensity variance \( \sigma_g \) and the output efficiency \( \eta \) are as follows: \( \sigma_g = 2.9 \times 10^{-3} \) (6.59×10^{-3}), \( \eta = 96.46 \% \) (89.72 %) for \( M = 4 \); \( \sigma_g = 3.7 \times 10^{-5} \) (1.98×10^{-5}), \( \eta = 93.63 \% \) (91.2 %) for \( M = 100 \). The calculation of \( \sigma_g \) was performed by a formula analogous to (4), but for intensities.
I note that, in the calculation of a kinoform-former of a SG, a special attention should be paid to a choice of \( r_0 \) defining the effective width of a beam illuminating the kinoform. For small \( r_0 \), the kinoform is illuminated by a narrow Gauss beam, which means the actual nullification of light amplitudes on the edges of the kinoform. This is equivalent to a reduction of the band of space frequencies forming a SG. As a result, the pattern of a SG will be covered by a speckle irrespective of the value of \( r_0' \) (see Fig. 6). In more details, the problem of restriction of the frequency band and its relation to the quality of images are considered in [4].

4. Conclusions

Thus, the weighting algorithm has high efficiency in the synthesis of the kinoforms of binary objects. It is basically important that the effect of stagnation of the algorithm is absent in this case, i.e., the one-bits variance \( \sigma_g(k) \) in a reconstructed image tends to zero with increase in the number of iterations and the noise level (zero-bits) is the same as that of other algorithms or lower. The weighting algorithm is also efficient in calculations of kinoforms as the formers of SG laser beams. It must be emphasized that the weighting algorithm contains no parameters requiring the optimization (like \( \beta \) in the IO algorithm), which essentially accelerates the counting rate. However, it is expedient to apply this algorithm to half-tone objects only in the case where the minimum amplitude of the normalized distribution of an object is \( \sim 0.15-0.20 \).
